Abstract  Sediment cores recently collected from the Chilean Margin during D/V JOIDES Resolution Expedition 379T (JR100) document variability in shipboard-generated records of the green/blue (G/B) ratio. These changes show a strong coherence with benthic foraminiferal δ¹⁸O, Antarctic ice core records, and sediment lithology (e.g., higher diatom abundances in greener sediment intervals), suggesting a climate-related control on the G/B. Here, we test the utility of G/B as a proxy for diatom productivity at Sites J1002 and J1007 by calibrating G/B to measured biogenic opal. Strong exponential correlations between measured opal% and the G/B were found at both sites. We use the empirical regressions to generate high-resolution records of opal contents (opal%) on the Chilean Margin. Higher productivity tends to result in more reducing sedimentary conditions. Redox-sensitive sedimentary U/Th generally co-varies with the reconstructed opal% at both sites, supporting the association between sediment color, sedimentary U/Th, and productivity. Lastly, we calculated opal mass accumulation rate (MAR) at Site J1007 over the last ~150,000 years. The G/B-derived opal MAR record from Site J1007 largely tracks existing records derived from traditional wet-alkaline digestion from the south and eastern equatorial Pacific (EEP) Ocean, with a common opal flux peak at ~50 ka suggesting that increased diatom productivity in the EEP was likely driven by enhanced nutrient supply from the Southern Ocean rather than dust inputs as previously suggested. Collectively, our results identify the G/B ratio as a useful tool with the potential to generate reliable, high-resolution paleoceanographic records that circumvent the traditionally laborious methodology.

Plain Language Summary  The color of marine sediments often corresponds to oceanic and sedimentary processes that can influence the global climate system. Visual inspection of new sediment cores collected from the Chilean Margin revealed substantial downcore changes in green and blue sediment colors. Greener sediment intervals were usually enriched with diatoms, whereas bluer sediments were rich in clay minerals. A specialized camera was used to scan the cores and enable us to quantitatively describe the core colors using the green/blue (G/B) ratio. The similarity of the downcore G/B ratio with Antarctic ice core records suggests that it may serve as a quick tool to estimate the age of the cores during the cruise. In this paper, we show that changes in the G/B ratio are a function of diatom (biogenic opal) productivity and use a calibrated relationship to calculate a continuous record of opal flux at the Chilean Margin over the last 150,000 years. A distinct opal flux maxima at 50,000 years ago is observed, similar to previous studies in the eastern equatorial Pacific. This common event implies a tight link between the high- and low-latitude eastern Pacific Ocean, potentially attributable to enhanced nutrient supply from the Southern Ocean.

1. Introduction

Variations in Southern Ocean and South Pacific primary productivity have been invoked as possible drivers of glacial-interglacial climate change and atmospheric CO₂ variability (Brzezinski, 2002; Matsumoto et al., 2002; Sigman & Boyle, 2000; Toggweiler et al., 2006). Our understanding of the role primary productivity plays in the climate system on these timescales is partly attributable to records of opal mass accumulation rates (MAR) in marine sediments (Anderson et al., 2009; Bradtmiller et al., 2009; Charles et al., 1991; Dubois et al., 2010). Many of the records spanning glacial timescales, however, do not have adequate resolution to resolve (sub)millennial-scale changes, which have been shown to influence both the inception and termination of glacial periods (Jouzel et al., 2007). This is partly because the traditional wet-alkaline methods that are used to derive
these records are laborious (e.g., Mortlock & Froelich, 1989), which limits the viability of generating continuous, high-resolution records of opal MAR across glacial-interglacial intervals.

One potential avenue to circumvent this obstacle and generate high-resolution opal MAR records is by utilizing the color spectrum of marine sediments derived from core image scanning and spectrometry (Mix et al., 1995; Nederbragt et al., 2000). Generation of sedimentary reflectance spectrometry records upon core recovery is standard for most paleoceanographic coring operations and can provide millimeter-scale resolution of sediment properties (e.g., Mix et al., 1992). These data are often calculated as L* (total light reflected), a* (blue and green), and b* (red and green) values, which have been widely used for core stratigraphy and paleoceanographic reconstructions (e.g., Peterson et al., 2000). For example, Mix et al. (1992) documented a close correlation between high Red/Blue ratios (calculated as b*/a*) and the presence of sulfides in eastern equatorial Pacific (EEP) marine sediment. However, the RGB data extracted from digital section images may be of equal utility since variations in the sediment color often correspond to key oceanic or sediment processes (e.g., primary productivity, terrigenous input, and sediment diagenesis; Nederbragt & Thurow, 2005). Penkrot et al. (2018) reported that the green/blue (G/B) ratio closely tracks biogenic opal in sediment cores taken from the Gulf of Alaska. While these are important observations, the established relationships are qualitative. To leverage these records with potentially millennial- or sub-orbital-scale resolution for reconstructing regional primary productivity, an empirical relationship between RGB variables (e.g., G/B) and a lithologic component (e.g., biogenic opal) must be established.

Recent drilling operations on the south Chilean Margin (D/V JOIDES Resolution Exp. 379T funded through the NSF JR100 program) recovered piston cores to a maximum depth of 100 m to investigate (sub)millennial-scale to glacial-interglacial variability since the penultimate glaciation. Here, we utilize sites J1002 and J1007 (Figure 1).
which document millennial-to sub-orbital-scale changes in the sediment G/B ratio. The G/B data were initially used onboard as a stratigraphic tool owing to similarities with global climate records (e.g., EDML ice core (the European Project for Ice Coring in Antarctica [EPICA] Dronning Maud Land ice core; EPICA Community Members, 2006). Shipboard lithologic analyses subsequently revealed that sediments enriched with diatoms coincide with high green values, whereas clay-rich sediments corresponded with high blue values (Figure 2). Thus, G/B records in Chilean Margin cores may serve as a paleoceanographic archive of opal percentage in regional sediments.

In this paper, we first explore the conceptual background of the proxy itself, as well as the rationale for using G/B in our stratigraphic efforts. We then test the hypothesis that the G/B record correlates with opal content in sediments on the Chilean Margin by calibrating the proxy to biogenic opal concentrations quantified by traditional methods (Mortlock & Froelich, 1989). Lastly, we use the G/B records and initial core stratigraphy based on radiocarbon ages and benthic oxygen isotope records to generate continuous opal MAR records for the last ∼150,000 years at Site J1007, offering the highest resolution record of diatom productivity in the south Pacific Ocean through most of the last glacial cycle.

2. Materials and Methods

2.1. Geological and Oceanographic Settings

Our study region in the southeast Pacific Ocean ranges from the central to south Chilean Margin, where the northward deflection of Antarctic Circumpolar Current (ACC) forms the Peru-Chile Current (PCC; a.k.a Humboldt Current) between 40°S and 45°S (Strub, 1998). The northward flowing PCC dominates the surface circulation pattern along the west coast of South America (Figure 1). The poleward flowing Gunther Undercurrent underlies the PCC between 100 and 400 m water depth (Hebbeln et al., 2000; Strub, 1998). Between 500 and 1,200 m water depth flows Antarctic Intermediate Water (AAIW), which forms today at the Subpolar Front by mixing cold, fresh Polar Front waters with Subantarctic Mode Water (Piola & Georgi, 1982; Sallée et al., 2010; Sloyan & Rintoul, 2001). Beneath AAIW sits the northern flowing Antarctic Bottom Water and sluggish Pacific Deep Water (PDW) return flow, which enters the Southern Ocean at mid-depths (Talley, 2013). Coastal upwelling is intensive throughout the year north of 35°S but is restricted to late spring and early fall between 35° and 42°S. South of 42°S, coastal upwelling is inhibited by the prevailing southern westerly winds (Strub, 1998).

The current oceanographic regime makes the Chilean Margin a remarkably productive region in the modern setting. Annual chlorophyll concentration in surface waters along the Chilean Margin reaches up to 4 mg/m³ (Figure 1b). Annual primary productivity in this region is dominated by diatoms (Abrantes et al., 2007), and based on satellite-measured pigments is estimated to about ∼150 gC/m²/yr off central Chile (31°–37°S) and ∼60 gC/m²/yr along the south Chilean Margin (i.e., south of 37°S; Antoine & Morel, 1996). The latitudinal distribution pattern of opal contents (opal%) and organic carbon contents (Corg %) in surface sediment samples reflect the overlying pigment concentration; surface sediment opal% ranges from ∼5% off central Chile to ∼3% in the south (Romero & Hebbeln, 2003). Despite the high diatom productivity in this region, theopal percentages in the sediments are very low because of the extremely high sedimentation rates on the margin, which can exceed 200 cm/kyr (Hebbeln et al., 2007). High sedimentation rates along the Chilean Margin are largely attributable to significant regional precipitation and high elevations of the Coastal Range and the Andes. Precipitation can vary from <1,000 mm/yr in central Chile to >2,500 mm/yr south of 40°S, leading to increased terrigenous supply in the south (Stuut et al., 2006).
2.2. Study Sites

Sites J1002 and J1007 were recovered from the Chilean Margin using the D/V JOIDES Resolution drilling platform during Expedition 379T in Summer 2019 (Figure 1). Site J1002 (46° 4.2964′S and 75° 41.2300′W) is located on the south Chilean Margin offshore Northern Patagonia on a bench in the continental slope at a water depth of 1,534 m. At present, this site lies under the northern extent of the ACC and is bathed in PDW. Site J1007 (36° 32.5400′S and 73° 39.9900′W) is located on the continental crust 60 km shoreward of the Chile Trench. With a water depth of 781 m, Site J1007 lies in the heart of modern AAIW (Bova et al., 2021).

Recovered sediments at both sites are assigned to single lithologic units composed primarily of Pleistocene silty clay. Variations of clay contents were presented by natural gamma radiation (NGR) at both sites (Figures S1 and S2 in Supporting Information S1), as higher NGR usually correlated to higher clay contents (Rosenthal et al., 2018). There is a general downhole trend of decreasing NGR at Site J1002 and increasing NGR at Site J1007. Minor biogenic components (primarily diatoms and second foraminifera and nannofossils) and frequent presence of sulfide minerals were found at both sites (Figures S1 and S2 in Supporting Information S1). At J1007, large (2–10 cm) carbonate concretions were found at ∼59 and ∼97 m, close to the intervals with prominent low magnetic susceptibility. Overall, the dominance of siliciclastic component reflects hemipelagic sedimentation at the two sites (Bova et al., 2021).

2.3. Age Models

Age models for Site J1002 and J1007 (Figures S3 and S4 in Supporting Information S1; see age control points in Table S3 in Supporting Information S1) were based on a combination of AMS radiocarbon dating and the visual correlation of δ18O records of benthic foraminifera to the LR04 benthic stack (Lisiecki and Raymo, 2005). Calendar ages for the upper parts of the core are based on AMS 14C dating of planktonic foraminifera (Globigerina bulloides); eight in the upper 67 m of Site J1002 and seven in the upper 23 m at Site J1007, with calendar corrections using IntCal20 (Reimer et al., 2020, Figure 3). Below these depths, stratigraphy is based on visual correlation between benthic foraminifer Uvigerina spp. δ18O and the LR04 benthic stack. The Undatable program has been used to refine the original age models (Lougheed and Obrochta, 2019), improving the resolution and...
precision of the opal flux estimate simultaneously (see age-depth figures in Figures S3 and S4 in Supporting Information S1). Comparison with benthic δ¹⁸O from the nearby ODP Site 1234 (36°14'S and 73°41'W, 1.015 m; de Bar et al., 2018; Heusser et al., 2006; Robinson et al., 2007) is further applied to constrain the J1007 age model. Nonetheless, we note that the J1007 age model below 66 m is loosely constrained due to limited resolution of the benthic δ¹⁸O record. For J1007, the interval between 82 and 86 m is thought to represent the light δ¹⁸O “plateau” of Marine Isotope Stage (MIS) 5e. However, the δ¹⁸O of this recognized MIS 5e stage are not significantly more depleted than the Holocene as might be expected. Therefore, we caution that it is possible that the real MIS 5e “plateau” was missed due to low sampling resolution and the bottom of J1007 does not reach MIS 5e. This uncertainty has, however, no bearings on the discussion and conclusion of the paper but should be noted by potential users of the core data.

2.4. Sedimentary G/B Ratio

Although extremely high sedimentation rates along the southern Chilean Margin offer the opportunity to generate high-resolution paleoproductivity records, they also pose a few challenges. First, the concentration of biogenic components (e.g., organic carbon% and opal%) are very low (Figures S1 and S2 in Supporting Information S1), approaching the detection limits of the analytical methods. And second, taking advantage of the high sedimentation rates for generation of high-resolution records using traditional methods is laborious and practically unattainable. For example, to achieve ultra-high resolution in a 100 m sediment core would require collection and analysis of potentially 1,000 of samples. Therefore, scanning methods with 1-cm step can offer valuable information that cannot be obtained from traditional discrete measurements. The advantage of such a method is more in capturing the temporal variability at high resolution than in providing accurate concentrations. The sedimentary G/B ratio is a quantitative method to describe sediment color in the RGB channels of green and blue ranges (Nederbragt & Thuro, 2005). Digital section images were taken on the archive halves of the core using a line-scan camera on the automated Section Half Imaging Logger. Sediment cores were scraped using a glass slide after splitting, and the cleaned flat face of the archive half was immediately imaged to prevent color degradation at a resolution of 10 lines/mm. Data were presented as averaged digitized channels of red, green, and blue, with values ranging from 0 to 255 (Bova et al., 2021). The sedimentary G/B ratio was calculated as the green parameter divided by the blue parameter. It should be noted that the sediment color presented by the RGB channels is different from the L*, a*, b* tristimulus, as the previous one is extracted from digital section images and the latter one is calculated with spectral counts acquired using the light spectrophotometer.

Preliminary results of the shipboard smear slide description suggest a possible link between sediment color and lithology, in agreement with previous work (e.g., Mix et al., 1992, 1995; Nederbragt et al., 2000; Penkrot et al., 2018). Pigments are widely produced by marine algae like diatoms and coccolithophores (Leavitt & Hodgson, 2002). In our study sites, elevated abundance of diatoms is typically found in greener sedimentary intervals (Figure 2). Similar latitudinal distribution patterns of opal%, Corg%, and pigment concentrations suggest that diatoms are the dominant group of primary producers along the Chilean Margin (Abrantes et al., 2007; Romero & Hebbeln, 2003; Stuut et al., 2006), thus contributing most part of the pigments in sediments. The primary pigments of diatoms are the green chlorophyll-a and the blue-green chlorophyll-c (Kuczynska et al., 2015; Stau and Jeffrey, 1988). Although chlorophyll can be degraded, most of the breakdown products (e.g., chlorins) are still detectable by regular spectrophotometric methods (Reuss et al., 2005). Indeed, downcore pigment records have been used to reconstruct productivity changes in lakes and estuaries for decades (Reuss et al., 2005, 2013). Thus, it has been hypothesized that the color of green is mainly produced by diatom-related pigments in this region. In contrast, cores with a dominance of siliciclastic components and a lower abundance of diatoms are usually found to be bluer (Figure 2). Considering the tremendous terrestrial input commonly found along the Chilean Margin, the siliciclastic component likely produces the blue color. We therefore hypothesize that the sedimentary G/B ratio reflects the relative abundance of biogenic silica in sediments, and based on our calibration, can use it as to quantify diatom productivity along the Chilean Margin over time.

Given the high-temporal variability of the records, the sedimentary G/B ratio has also been a useful tool for stratigraphic correlations among holes drilled during Expedition 379T because it is likely linked to regional climate processes (Bova et al., 2021). Previous studies suggest that Antarctic climate changes have a significant impact on surface water dynamics and terrestrial input off the coast of Chile (Lamy et al., 2004; Kaiser et al., 2007). Regional surface water processes are closely linked to diatom production, hence the green parameter
of the sediments. On the other hand, the terrestrial input is assumed to contribute to the blue parameter in sediments. The variation of sedimentary G/B ratio may be sensitive to climate dynamics, making it applicable for stratigraphic correlations. To validate these assumptions, we compare the downcore variations in G/B at J1002 and J1007 with the benthic foraminiferal δ¹⁸O record at each site. The remarkable consistency between the G/B and benthic δ¹⁸O at both sites validates the use of the G/B ratio for stratigraphic correlations along the Chil-lean Margin (Figure 3). Moreover, G/B ratios at both sites show good correlations with Antarctic ice core δ¹⁸O records, with higher G/B values usually corresponding to warm intervals near Antarctica and lower G/B values corresponding with cold intervals; this observation further demonstrates its utility for stratigraphic correlations (Figure 3). This tool has been especially useful for shipboard correlation as other sedimentary property records in these regions (e.g., magnetic susceptibility, NGR, and other color properties) had muted signals. For example, magnetic susceptibility was widely used for shipboard correlation among holes, but for high sedimentation rate sites—especially those with thick Holocene section that were devoid of any appreciable magnetic susceptibility signal—G/B ratios turned out to be the most applicable stratigraphy tool (Bova et al., 2021).

2.5. Biogenic Opal Analyses

J1002 and J1007 were sampled at intervals spanning the range of G/B values measured at each site to investi-gate the relationship between opal% and G/B. Biogenic silica concentrations were measured by conventional wet-alkaline digestion, including mineral correction procedures modified after Conley and Schelske (2001). The mineral correction was critical for sediments with relatively low biogenic silica contents as it minimizes the effect of mineral silicates. A total of 22 samples from J1002 and 41 samples from J1007 were analyzed. About 250 mg of freeze-dried sediments were homogenized using a mortar and pestle and digested by 1 mol/L Na₂CO₃ solution in an 80°C water bath. The tubes were shaken quickly for complete digestion every 20 min. Subsamples of 1 mL were taken after 3, 4, and 5 hr of digestion time. Silicate concentration of each subsample was measured by molybdate blue spectrophotometric measurements using an Agilent Cary 60 UV-vis Spectrophotometer at Rutgers University peaked at 812 nm, modified after Mortlock and Froelich (1989) (see detailed experimental and data processing procedure in Text S1 in Supporting Information S1). Ideally, a linear regression was made with the three subsamples, with extrapolation to the intercept providing the final biogenic silica concentration (DeMaster, 1979). Finally, opal% was calculated as biogenic silica concentration multiplied by 2.4 (Mortlock and Froelich, 1989). The standard error of our measurements was 0.35% based on 14 duplicate measurements. Wet-alkaline digestion could be affected by “noise” from clay (Conley & Schelske, 2001). Our mineral correction protocol suggests, however, that clay only contributes to a stable background noise of 0.3% (Figure S5 in Supporting Information S1), which was then removed during the data processing procedure.

2.6. Quantifying U and Th Contents With Shipboard Natural Gamma Radiation Data

Full NGR data for Site J1002 and J1007 were collected during Expedition 379T. Original NGR spectra obtained on board were composed of numerous peaks for the ²³⁸U and ²³²Th series. Thus, sedimentary contents of thorium (²³²Th), and uranium (²³⁸U) were estimated by identifying and quantifying their characteristic energy peaks using a MATLAB algorithm by De Vleeschouwer et al. (2017). Note that the values reported here are concentration values instead of activity values. De Vleeschouwer et al. (2017) reported the precision of the algorithm as the correlation coefficient between calculated contents and contents measured by mass spectrometry (ICP-MS), which is 0.89 for Th and 0.84 for U based on 245 samples. The accuracy was evaluated by the slope and intercept of the regression line, suggesting a slight overestimation of Th and highly accurate estimates of U content.

3. Results and Discussions

3.1. Calibration of Sedimentary G/B With Measured Opal%

Shipboard sedimentary G/B records exhibit a generally northward increasing trend along the Chilean Margin, in agreement with annual chlorophyll distribution in surface waters (Figure 1b). In addition to lower average values, the G/B for Site J1002 also shows smaller variabilities than J1007. Measured opal% for Site J1002 and Site J1007
vary between 0.36%–4.36% and 1.89%–5.35%, respectively. In general, measured opal% covary with the G/B, with higher measured opal% usually found in greener sediments (Figure 4a). Eight samples from J1007 and one sample from J1002, however, apparently underestimate opal% with respect to G/B (Table S2 in Supporting Information S1). In all cases, these intervals are associated with prominent low values of magnetic susceptibility (Figure 5), which hints to the possibility of diagenetic overprints. This marked decrease of magnetic susceptibility is a widespread phenomenon in sediments of the continental margin, and is usually caused by diagenetic processes within the zone of anaerobic oxidation of methane (Johnson et al., 2021; Riedinger et al., 2005). Distinct diagenetic processes may further induce color alteration of the sediments (Giosan et al., 2002), resulting in mismatch between G/B and measured opal% at these intervals.

At Site J1007, the organic carbon percentage (C$_{org}$%) correlates well with measured opal% ($n = 21$, $r^2 = 0.51$, $p < 0.05$; Figure 4b), in agreement with the robust correlation between opal% and C$_{org}$% in the nearby surface sediments (Romero & Hebbeln, 2003). Those samples with potentially underestimated opal%, within low magnetic susceptibility intervals, are similarly offset from the expected values based on average correlation between opal% and C$_{org}$%. Preliminary shipboard analysis shows the frequent presence of nannofossils and diatoms in sediments along the Chilean Margin (Bova et al., 2021). Discrete measurements onboard suggest that CaCO$_3$% range from 1% to 5% for Site J1007 and 0.3% to 8% for Site J1002 (Figures S1 and S2 in Supporting Information S1). But the nannofossils only contribute a minor part of the CaCO$_3$, according to estimates from the smear slides (see smear slide photos under cross polar light, Figure S6 in Supporting Information S1). Combining downcore and surface sediment records, it can be deduced that primary productivity in this area is dominated by diatomaceous species, with carbonate nannofossil species as a minor contributor. In contrast, C$_{org}$% shows only a weak correlation with G/B (Figure 4c), which suggests one or both indicators are impacted by degradation. Nonetheless, most degradation products of chlorophyll retain their original color (Reuss et al., 2005). The color properties of chlorins (a typical chlorophyll degradation product) are measurable by spectrophotometry method in Pleistocene sediments at various sedimentation settings (e.g., Cartagena-Sierra et al., 2021; Gebhardt et al., 2008; Harris et al., 1996; Hodgson et al., 2003), reaching timescales over million years and burial depths of hundreds of meters (Cartagena-Sierra et al., 2021; Gebhardt et al., 2008; Harris et al., 1996; Hodgson et al., 2003).
na-Sierra et al., 2021). It is likely the G/B proxy is a more robust indicator and possibly independent of organic matter preservation. Nonetheless, with these caveats in mind, data from low magnetic susceptibility intervals should be considered with higher uncertainty.
Excluding the underestimated data points (20% of entire data set, shown in Figure 5), strong exponential correlations are found between G/B and measured opal% at both sites (J1002: ln(y) = 5.8x−6.3, n = 14, r² = 0.73, p < 0.05; J1007: ln(y) = 5.8x−5.5, n = 22, r² = 0.48, p < 0.05; where x and y are G/B values and opal%; Figure 4a). The calibrations of J1002 and J1007 show the same slope but different intercept, indicating similar sensitivity of G/B and differences in background colors. Root mean square deviation (RMSD) were calculated based on the differences between measured opal% and the reconstructed opal% derived from G/B values. The RMSD is 0.68% for J1002% and 0.72% for J1007, reflecting the uncertainty of regression models in this study.

Note that while the relationships between G/B, opal%, and C_{org}% are robust, the empirical calibrations are site-specific to J1002 and J1007 and cannot be transferred to other sites, even those in the same region. We hypothesize that variable clay mineralogy along the meridional transect (e.g., Lamy et al., 1998) cause spatial differences in the total “blue” content in the sediments, which were presented by different intercepts of the calibration equations. Although climatically induced changes may substantially influence the mineralogy of the silicilastic inputs at both J1002 and J1007, such variability is unlikely to cause significant influences on the G/B. For example, chlorite could potentially contribute to the green coloration and is present as an important component of clay mineralogy at the central- and southern Chilean Margin (Lamy et al., 1998). But the chlorite content at ∼35°S shows a decreasing trend from the LGM to the Holocene (Lamy et al., 1999), opposing the variation of G/B record at Site J1007. Similar to X-ray fluorescence (XRF) scanning records of cores, the G/B ratio may also provide a semi-quantitative record that will require a site-specific calibration at each site to convert the relative changes to a record of opal%. It is noteworthy, however, that the two studied sites represent a specific case where the opal concentrations are very low due to dilution from the very high sedimentation rates. It is likely that the method and calibration would be more robust in sites where the contribution of clays and sedimentation rates are lower than those encountered on the Chilean Margin. But the calibrations with low opal% point to the potential utility of G/B proxy in a wide range of depositional settings.

3.2. Reconstructing Opal% Records

Having established the G/B proxy as a tracer of opal% at our study sites, we now use the exponential regression equations above to reconstruct past changes of opal% from the G/B records. Downcore opal% ranges between 0.6%−2.5% and 1.6%−8.8% for J1002 and J1007, respectively (Figure 5). Reconstructed opal% shows relatively large-scale variability at Site J1007, with the highest opal% for the past 150 kyr found during Termination II and MIS 3 (Figure 5a). At Site J1002, reconstructed opal% shows a prominent peak during Holocene, but remains low and stable before Last Glacial Maximum (LGM, 23–19 ka; Figure 5b). At Site J1002, opal% only ranges ∼1% before the LGM, which can be almost entirely attributed to reconstruction uncertainty (2*RMSD = 1.36%, see pink shading in Figure 5). Thus, we caution against the utility of the J1002 opal% reconstruction before the LGM and do not use it for paleoceanographic interpretation.

Over the past 30 kyr, opal% at J1007 and J1002 gradually increases from the last glacial period to the Holocene. During the late Holocene, J1007 opal% is 4%−5%, similar to the opal content of ∼5% in nearby surface sediments (Romero & Hebbeln, 2003). Meanwhile, J1002 opal% of about 2.5% during the Holocene agrees with opal contents of ∼4% in surface sediments at 44°S (Chase et al., 2015; Romero & Hebbeln, 2003). The opal% range for J1007 over the last 30 kyr (2%−6%) is similar to that of two nearby sites, and the variation trend mimics GeoB 3395-3. At Site J1002, the low opal% prior to the last glacial period is attributable to a marked increase in sedimentation rate (>3 m/kyr), which appears to significantly dilute the opal% relative to the Holocene.

Previous opal% reconstructions along the Chilean Margin only covered the past 30 kyr, and vary in similar range but with different patterns. On the central Chilean Margin, site GeoB 3395-3 (35°13′S and 72°48.5′W, 678 m) has opal% ranging from ∼1.5% to 5% for the past 23 kyr, with the highest values appearing during late Holocene (Romero & Hebbeln, 2003; Romero et al., 2006). The opal% at ODP Site 1234 (36°14′S and 73°41′W, 1,015 m) range from ∼2% to 5% for the last 30 kyr, with peak values occurring during the last glacial period (26–20 ka), but slightly before LGM (Chase et al., 2014). Moreover, it is worth noting that the chlorins content at nearby site GeoB 7165-1 (36°33′S and 73°40′W, 797 m) also increases from the LGM to late Holocene (Mohtadi et al., 2008). Further south, the diatom abundance record from ODP Site 1233 (41°S and 74°27′W, 838 m) is very similar to that of ODP 1234 (Chase et al., 2014). Overall, the consistent range of reconstructed opal% at J1002 and J1007 with nearby sites strongly support the robustness of sedimentary G/B-opal% proxy.
3.3. Sedimentary U/Th

In nature, thorium occurs almost entirely as $^{232}$Th while uranium primarily exists as $^{238}$U, both of which are primarily supplied to the oceans by riverine runoff (McManus et al., 2006). As a non-redox-sensitive metal, $^{232}$Th has low solubility in rivers and oceans, and is largely absorbed on the surface of clay minerals (Harmsen & De Haan, 1980). On the other hand, $^{238}$U exist as both soluble U(VI) and insoluble U(IV) phases (Langmuir, 1978). In oxygenated seawater, $^{238}$U is present dominantly as a stable U(VI) carbonate complex, with a small fraction associated with particulate organic carbon flux (McManus et al., 2005). Under suboxic conditions, authigenic U accumulates in the sediments as a combination of the bio-authigenic phase associated with settling organic particles and that formed by diffusion of U into sedimentary pore waters (Barnes & Cochran, 1990; Henderson & Anderson, 2003; McManus et al., 2005). Therefore, sedimentary U/Th, which minimizes the influence of variable detrital sources and sedimentation rates (thus the authigenic U burial rate), can be used as a non-quantitative indicator of redox conditions of the sediments.

Both the thorium and uranium contents are higher at Site J1002 than Site J1007, corresponding to larger terrestrial input to the south Chilean Margin. In contrast, U/Th at Site J1007 was found to be higher than that of J1002 (Figure 5). Higher U/Th reflects more suboxic sedimentary conditions (referring to low dissolved oxygen availability in bottom waters), high organic carbon rain rates, or some combination of both processes (McManus et al., 2006). We observe marked similarities in both trends and magnitudes between measured opal%, G/B-reconstructed opal%, and U/Th profiles at both sites (Figure 5). Authigenic U MARs were also calculated with different assumptions of lithogenic U/Th ratio at J1002 and J1007 (Figure S7 in Supporting Information S1). The authigenic U MAR generally tracks the changes of bulk U/Th at J1007, with increased authigenic U MAR found at the intervals with low magnetic susceptibility. As mentioned before, marked decrease of magnetic susceptibility is widely linked to diagenetic processes within the zone of anaerobic oxidation of methane (Johnson et al., 2021; Riedinger et al., 2005), likely resulting in elevated U precipitation. At J1002, calculated authigenic U MARs show different patterns to bulk U/Th, suggesting dominant control of sedimentation rate at this site. Taken together, the co-occurrence of high productivity intervals (high opal%, high G/B) and suboxic conditions, as indicated by high U/Th, supports the use of G/B as a proxy of diatom productivity on the Chilean Margin.

3.4. Reconstructed Opal MAR

Previous studies along the Chilean Margin provide only short and relatively low-resolution records of opal MAR (Chase et al., 2014; Hebbeln et al., 2002; Mohtadi & Hebbeln, 2004; Romero et al., 2006). To fill the research gap on sub-orbital-scale variability in diatom productivity, we generated opal MAR records with G/B-derived opal% from Site J1007. Opal MAR at Site J1002 was also calculated for comparisons between J1007 and J1002. Opal MAR was calculated as:

$$\text{Opal MAR = opal% } \times \text{ } \rho_{\text{dry}} \times \text{LSR}$$  \hspace{1cm} (1)

where the opal% is calculated from the calibrated sedimentary G/B ratio, $\rho_{\text{dry}}$ is the shipboard-measured dry bulk density of the sediment (g/cm$^3$), and LSR is the linear sedimentation rate (cm/kyr) as established by J1007 age model. $^{230}$Th-normalization was not applied in this study considering that uncertainties inherent in normalization are especially critical for continental margin sediments with shallow water depth and tremendous lithogenic input (Francois et al., 2004).

In general, the sedimentary record of opal MAR shows large-amplitude variation at Site J1007 (Figure 6). Over the last 30 kyr, opal MAR of 2–3 g/cm$^2$/kyr were found before the LGM, which decreased to $\sim$1 g/cm$^2$/kyr during the deglaciation and into the Holocene. The opal flux records from two adjacent sites (GeoB 3395-3 and ODP Site 1234) show a distinct peak of $\sim$1.5 g/cm$^2$/kyr during the LGM (Figure 6a; Chase et al., 2014; Romero et al., 2006). Further south, opal MAR from ODP Site 1233 reaches a peak during the last glacial period (1.8 g/cm$^2$/kyr) and decreases below 0.2 g/cm$^2$/kyr since 20 ka (Chase et al., 2014). Note that $^{230}$Th normalization was applied to opal MAR calculations at ODP Site 1234 and ODP Site 1233, but not at GeoB 3395-3. The opal MAR variation of Site J1007 shows higher levels with longer duration than observed at the other three nearby sites. The difference may be due to the difference in the data sources. The J1007 record is based on continuous high-resolution G/B ratio, whereas the other records are based on low-resolution discrete wet analyses (Figure 5).

In fact, comparing the latter with our discrete samples from J1007 suggests a greater consistency among the...
Figure 6. Downcore opal mass accumulation rate (MAR) records from the eastern Pacific Ocean. (a) Opal MAR variation for the last 30 ka at GeoB 3395-3 (yellow; Romero et al., 2006), ODP Site 1234 (pink; Chase et al., 2014), and ODP Site 1233 (blue; Chase et al., 2014). Site J1007 (green) opal MAR are shown as smoothed solid curves (MATLAB loess smoothing, window = 50) with the ±1 uncertainty envelope (by error propagation from 1 RMSD). Gray markers show opal MAR calculated from measured opal% (closed circle) and data points from low magnetic susceptibility (open circle). (b) Opal MAR variation for the last 150 ka at Site J1007 (green) and V19-30 (orange; Hayes et al., 2011). Linear sedimentation rate (LSR) for Site J1007 is shown in the bottom panel. The MIS three peak in opal flux is highlighted with pink shadings. The dashed arrow shows potential correlation between the Site J1007 and EEP opal MAR peak at Termination II based on benthic δ¹⁸O tuning.

The interval with increased dominance of robust species (Shemesh et al., 1989). The smear slide observation shows no significant changes in the diatom assemblage during MIS 3 at Site J1007. On the other hand, enhanced opal preservation related to dust flux (Dubois et al., 2010) have been discussed as possible drivers for the 50-ka flux peak in the EEP, but are unlikely to influence sites at the Chilean Margin. Different from the two clear dust flux peaks during MIS 4 and MIS 2 at the central and the EEP (Winckler et al., 2008), the Fe concentration record from central Chilean margin show higher frequency variability during MIS 2-4 (Kaiser & Lamy, 2010). Therefore, a common opal flux maxima along the eastern Pacific basin are further echoed by a Diol index record offshore Southeastern Australia, which indicates maximum Proboscia diatom abundance during MIS stages 1, 3, and 5e (Lopes dos Santos et al., 2012).

Previous studies consider enhanced opal preservation as an important contribution to opal MAR in addition to diatom productivity (e.g., Dubois et al., 2010; Tréguer & De La Rocha, 2013). Dissolution is usually found in the interval with increased dominance of robust species (Shemesh et al., 1989). The smear slide observation shows no significant changes in the diatom assemblage during MIS 3 at Site J1007. On the other hand, enhanced opal preservation related to dust flux (Dubois et al., 2010) have been discussed as possible drivers for the 50-ka flux peak in the EEP, but are unlikely to influence sites at the Chilean Margin.

Increased contribution of northern hemisphere waters with higher Si:N has been ruled out as the main control on the EEP opal flux maxima during MIS 3 (Hayes et al., 2011; Kienast et al., 2006), and is less likely a significant source to mid-latitude South Pacific. Therefore, this common 50 ka event along the eastern Pacific meridional transect, paired with a peak diatom productivity offshore Southeastern Australia, implies a climatic connection between the high and low latitudes in the Southern Hemisphere, likely through nutrient-rich intermediate waters exported from the Pacific-sector...
of the Southern Ocean (Talley, 2013). Southern Ocean Intermediate Waters supply nitrogen, phosphorous, and silicate to the global thermocline, thereby supporting up to 75% of tropical production (Ayers & Strutton, 2013; Sarmiento et al., 2004). The widely presented MIS opal flux peak supports the idea of enhanced Si supply to low latitudes (Hayes et al., 2011), depicting a clear route of “oceanic tunneling” between the Antarctic and the equatorial Pacific (Pena et al., 2008; Spero & Lea, 2002). Moreover, the opal flux at Site J1007 is nearly 10 times greater that of EEP records, implying that mid-latitude continental margins could have served as an important sink for leaking Si from the glacial Southern Ocean (Bradtmiller et al., 2009).

4. Conclusions

Diatom production plays a major role in the biological pump, especially in the Southern Ocean and upwelling regions such as along the EEP and western margins of South American. However, because measuring opal% in sediment is analytically very laborious, obtaining high resolution sedimentary records of opal accumulation is practically impossible, especially in cores with very high-sedimentation rates like those along the Chilean Margin. This study demonstrates that using shipboard measurements of the sedimentary G/B ratio from newly recovered sediment cores on the Chilean Margin, coupled with calibration of discrete samples using traditional methods, can offer a new approach to generate high-resolution paleoceanographic records for reconstructing glacial-interglacial changes in South Pacific diatom productivity. In more detail, we conclude the following:

1. The sedimentary G/B ratio in Chilean Margin sediments can serve as an efficient shipboard stratigraphic tool, where other shipboard data (e.g., magnetic susceptibility) are not conclusive.
2. The G/B records provide high-resolution proxy records for regional changes in diatom productivity over time. The conversion of G/B data to opal% records requires site-specific calibrations from discrete opal% analysis using traditional wet-alkaline digestive methods. Offsets among sites in the G/B ratio to opal% relationships are likely related to lithological effects. Nevertheless, the records suggest that, despite diagenetic effects on biogenic silica and organic matter preservation, the G/B records may more reliably record paleoproductivity, especially in very high sedimentation rates environments where their concentration are diluted.
3. Continuous records of opal MAR on the Chilean Margin over the last ∼150,000 years largely tracks existing records from the EEP, with a common opal flux peak at ∼50 ka. This suggests a climatic link between high and low latitudes in the South Pacific through intermediate waters.
